(54) **Method of electronic scanning**

(57) The system achieves high-resolution imaging with low-resolution two-dimensional imagers whose sensors are only a fraction of a selected pixel area. Sensors are stepped across an image with an optical or mechanical stepper to acquire an image at each sensor position. Thereby, resolution is defined by a step size which is comparable to the sensor size, rather than by

pixel resolution. The system thus uses multiple image obtained from individual sensors, which have a sensed area substantially less than the area of the pixels of a sensor array (34). Such rescanning is accomplished by movable mirrors or lenses (22,24,26,32) that are disposed between an illuminated specimen (20) and a sensor area (34).

EP 0 748 108 A2

Description

The present invention relates to a method of electronic imaging, and more particularly to obtaining high-resolution images using relatively low-resolution image sensor arrays.

The invention is particularly applicable to digital image acquisition arrays that have a relatively small area from which they derive their information, which area is relative to an entire pixel area as defined on a specimen.

The invention will be described with particular reference to obtaining such a resolution translation. However, it will be appreciated that the invention has broader application such as obtaining additional or redundant information during the scanning process so as to allow a higher-definition or integrity image capture.

Much of the work associated with present-day image acquisition, manipulation, and printing is done via digitization. However, hard or printed copy is still an essential step in most applications.

Conversion between hard copy images and digital representations thereof are accomplished by scanners. Such scanners typically include a sensor array such as charge-coupled devices ("CCDs"). In such CCD arrays, a real image of a specimen is focused onto a planar array. Each CCD element of the array provides a digital signal representative of light exposed thereto. Fabrication techniques inherent in CCD construction provide a finite distance between respective elements of the array. Thus, each array element provides a digital signal representative of a subportion of the corresponding image resultant from the associated specimen. Information provided in image interstices is therefor lost. This results in lessened image integrity or degradation by loss of this associated, visual data.

The object of the present invention is to provide a new and improved system which overcomes the above-referred problems, and others, and provides a digital image acquisition system which allows for capture of high-resolution images by use of multiple scan from sensors of individual sensor elements of sensor arrays.

In accordance with the present invention, an enhanced resolution image scanner includes an array of sensors. Each sensor of the array generates a signal representative of light energy focused on it. Light reflected from an associated specimen is communicated to the array of sensor elements. Each sensor element thereafter generates a signal representative of a corresponding picture element ("pixel"), of the associated image. Thereafter, the associated specimen is reoriented relative to the sensor array. With such reorientation, each sensor element of the array obtains another signal representative of a second, unique portion of the same specimen. A combination of both data sets thereafter provides a high-resolution, digitized image of the associated specimen.

In accordance with a more limited aspect of the subject invention, the reorientation of the sensor array rel-

ative for the specimen for acquiring the second signal is done such that each sensor acquires a second reading taken from a different portion of the same pixel from which that sensor obtained the first reading. This is suitably accomplished by either rotating mirrors or rotating lenses disposed between the sensor array and the associated specimen.

In accordance with another aspect of the present invention, the second signal from each of the sensors is obtained from another pixel, other than that from which the particular sensor element obtained its first reading. This is suitably accomplished by mirrors disposed between the sensor array and the associated specimen. The movements of mirrors accomplish the required displacement.

An advantage of the present invention is the provision of a system by which higher-resolution image acquisition may be accomplished by a relatively coarse array of sensor elements.

Yet another advantage of the present invention is the provision of a system which matches actual acquired image data with the desired resolution of an associated, captured image.

Yet a further advantage of the present invention is the provision of an image acquisition system which provides additional or redundant information which is combined and provided in the resultant, capture image.

The present invention will be described further, by way of examples, and with reference to the accompanying drawings wherein:

FIGURE 1 illustrates 3X enhancement in effective resolution accomplished by stepping a sensor with respect to an image and doing multiple scans;
FIGURE 2 illustrates a system for stepping an image of a document on a two-dimensional sensor array with two rotating wedges;
FIGURE 3 illustrates light refraction as implemented in the structure of FIGURE 2;
FIGURE 4 illustrates sensor mapping for a 2X resolution enhancement operation;

FIGURE 8 illustrates a schematic for 2X resolution imaging of a document by multiple scanning with a super-pixel sensor structure, wherein the array is stepped horizontally;
FIGURE 9 illustrates a schematic for 2X resolution imaging of a document by multiple-scanning, implementing a super-pixel sensor structure with an array being stepped in a 45° angle with respect to gate lines or data lines;
FIGURE 10 illustrates 3X resolution imaging of a

document by multi-scanning implementing a super-pixel sensor structure wherein the array is stepped horizontally;

FIGURE 11 illustrates a schematic of a superpixel sensor structure for NX resolution enhancement wherein the array is stepped in a horizontal direction;

FIGURE 12 illustrates a system for using a vibrating mirror to introduce a linear translation of a document image on a two-dimensional sensor array;

FIGURE 13 illustrates a stepping of an image of a document on a two-dimensional sensor array with lateral translation of projection lens;

FIGURE 14 provides a layout example of a super-pixel structure for a 3X resolution enhancement array;

FIGURE 15 illustrates a linear stepping of an array for a 3X resolution enhancement with a conventional pixel design; and

FIGURE 16 illustrates a high-resolution color imaging with a reduced data rate.

FIGURE 1 illustrates the basic methodology by which 3-times ("3X") enhancement in effective resolution is accomplished by stepping a sensor with respect to an image and doing multiple scans. When a size of a sensor is smaller than that of a pixel in an array, a resolution of the sensor array is defined by the pixel size. The subject system modifies this. The resolution is thereby dictated by the sensor size instead by stepping the sensor such that an image is made with multiple scans.

As evidenced by FIGURE 1, a pixel boundary for sensor position 1 on arbitrary sensor position 1 is depicted at 10. In FIGURE 1, the sensor size is assumed to be equal to a step size. In an actual practice, it is advantageous to have a sensor size designed to be somewhat larger than a step size. With this, there is some overlap in a sampled image among neighboring pixels (after reconstruction with multiple scans). Such an overlap serves to reduce moire' effects in a resultant scanned image. For simplicity and clarity in the drawings, the sensor size is illustrated to be the same as the step size.

The subject application teaches several ways to translate an image with respect to a sensor array. For example, stepping a sensor to various positions 1-9 within the pixel boundary 10 is illustrated in FIGURE 1. A first system that will be described includes a stepping-within-a-pixel method in which multiple positions of a single sensor cover a complete pixel area. A second system employs a super-pixel method. In this method, a super pixel is defined as several standard pixels. Sensor positions are patterned in a way chosen such that a linear translation of an image relative to a sensor array may be made. In both instances, a total area covered by a single sensor after completion of a scan process is larger or equal to the area of a pixel. First, the stepping-

within-a-pixel method will be described in detail.

A stepping-within-a-pixel method serves to position an array with respect to an image such that the sensor areas cover a complete area of an array pixel, such as evidenced in FIGURE 1. This is suitably accomplished with rotating glass wedges or rotating mirrors, both of which will be described below. It will be appreciated that any suitable optical manipulation can serve to accomplish the same result, such as by rotating a document and/or a sensor array in combination with a rotating wedge or a rotating mirror.

Turning to FIGURE 2, an implementation employing a rotating wedge system will be described in detail. One way to translate an image of a document with respect to a sensor array is by steering an image of the original with two rotating glass wedges. FIGURE 2 evidences this scheme. In the illustrated system, light from flash lamps 12a and 12b illuminate a document 20 placed at one focal plane of a lens 22. Light reflected from a spot on the document is thereby collimated by the lens 22. Thereafter, the light is bent by a series of translucent wedges 24 and 26 which share an optical path for light with a convex lens 22.

In the illustrated embodiment, wedges 24 and 26 are installed such that a top surface is generally perpendicular to an axis of rotation disposed at a center portion of each wedge. This advantageously coincides with an axis y of the common illumination path of light.

Turning to FIGURE 3, illustrated is an effect of a refractive wedge on a parallel light beam. A total refraction of a light beam $\Delta\alpha$ is caused by a wedge 30 with a wedge angle β and an index of refraction n is:

$$\Delta\alpha = (n-1)\beta, \text{ for small } \alpha$$

It will be appreciated that the properties evidenced by FIGURE 3 are experienced by both first and second wedges 24 and 26. It will be further appreciated that the bending $\Delta\alpha$ is independent of an angle of incidence α , when α is small. In other words, a set-up is not sensitive to wobbling of the wedges. Turning again to FIGURE 2, a second lens, illustrated as convex lens 32 results in a change of a beam angle that translates the image to a displacement of:

$$d = F\Delta\alpha$$

on the sensor array, where F is the total focal length of lens 32. For a 1:1 image magnification, a focal length of each of the two lenses is ideally identical.

By way of example, the system will be explained in conjunction with achieving a 2X enhancement of resolution. For a currently available 200 spi sensor array, a sensor size is typically 88 microns and a pixel size is 128 microns. By stepping a sensor into four quadrants of a pixel with the step size of 64 microns, one may ac-

quire an image at an effective 400 spi resolution. To move a sensor into four symmetrical positions, one need only use a single rotating wedge. A trajectory of the sensor position on a document is evidenced by FIGURE 4 by the circle 38. With a focal length of 30 cm., a selected wedge angle β should be about 1.7 arcmin (arc minutes), assuming $n=1.3$. To complete an image scan, a flash lamp should then be flashed when a trajectory has moved to the four positions 40(a), 40(b), 40(c), and 40 (d). These positions are evidenced by the dots 40 disposed on the circumference of the circle 38 in FIGURE 4. When this is accomplished, the four frames are then combined to form a scanned image with an effective 400 spi resolution.

To achieve an enhancement higher than 2x, a suitable embodiment employs two rotating wedges as illustrated above. With this embodiment, the wedges are rotate at different speeds. A trajectory of a sensor within a pixel is a vector superposition of trajectories caused by each wedge. If a center position of a sensor is chosen by to be the origin of a cartesian coordinate system (xy), its trajectory may be described as:

$$x = A \sin (2\pi f_1 t) + B \sin (2\pi f_2 + \phi); \text{ and}$$

$$y = A \cos (2\pi f_1 t) + B \cos (2\pi f_2 + \phi)$$

In these equations, A and B are amplitudes of trajectory displacement, which is proportional to an angle of the wedges. The values f_1 and f_2 are rotation frequencies of wedge 24 and wedge 26 respectively. The value ϕ (from the equation), is a phase difference between the wedges while t represents time.

For 3X enhancement in resolution, the following conditions apply:

$$A = B$$

$$\phi = 0; \text{ and}$$

$$f_2 = 5f_1$$

FIGURE 5 illustrates a trajectory of a system as described above.

Turning to FIGURE 6, a trajectory for a 4X resolution enhancement is described. With this system, the following operating conditions apply:

$$A = B$$

$$\phi = 0; \text{ and}$$

$$f_2 = 9f_1$$

In both cases, with a correct control of flash lamp exposure timing, one may position a sensor to different places within a pixel. Although a trajectory in both cases does not put the sensor to positions on an exact grid, this feature is suitably implemented to randomize sampling points by adding random noise in a timing signal for flash lamps. This is useful to reduce Moire' patterns when a scanner is imaging a half-toned image. For accurate construction of an image grid, it is advantageous interpolate for values on the grid. It will be appreciated that using even higher frequencies than that noted above, while keeping with the symmetry of trajectory, allows one to have sensor positions much closer to a desired grid. This serves to render offsets in sensor position to have an unnoticeable effect.

Turning now to FIGURE 7, an embodiment in which rotating mirrors are implemented instead of the rotating wedges described. It will be appreciated that the basic function of the wedges noted above is propagated forward, but being carried forward by reflective instead of refractive properties.

In the diagram of FIGURE 7, similar elements to that provided in FIGURE 2 have been provided with the same numbers. The basic distinction is in connection with the wedges 24 and 26 of FIGURE 2 which have been replaced with mirrors 50 and 52 in FIGURE 7. Thus, the mirrors serve to step the image. The common optical access y of FIGURE 2 is analogous to an optical path y' in FIGURE 7. Relative rotation frequencies in a two-mirror embodiment provide the same mathematical relationships disclosed above.

In addition to the foregoing, it will be appreciated that the same kind of image and motion may be achieved by moving either a document or a sensor array in a circular trace. It is also suitably implemented with a combination of a rotating wedge and a mirror. As long as two circular motion components at correct frequencies in a trajectory sensor movement are provided, the same effect is achieved. For example, suitable accommodations may suitably include (but are not limited to):

1. Moving both a document and a sensor array;
2. A moving document and a rotating wedge;
3. A moving document and a rotating mirror;
4. A moving sensory array and a rotating wedge; and
5. A moving sensor array a rotating mirror.

It will be recalled that for a 2X enhancement, one need only have one moving part in the system. It is suitably a circularly moving document, a circular moving sensing array, a rotating wedge, a rotating mirror, or the like.

Next, the super-pixel method noted above will be described in detail. The super-pixel method simplifies

motion required to a one-dimensional translation. It provides a super-pixel design for a sensor array. With particular reference to FIGURE 8, a scheme for a 2X resolution enhancement will be demonstrated. Such a super-pixel structure is evidenced in block 60. A superpixel is suitably chosen with a size that is twice that of a conventional pixel. A sensor in a second pixel (S_2) of a super-pixel 6 is off-set upward by one step size with respect to the first sensor (S_1). By stepping four times horizontally and interleaving four frames of images together in correct order, one image is provided with twice the spatial resolution of the array. In this instance, no interpolation is required. Numbers in the dash box 62 indicate a desired sequence for stepping.

FIGURE 9 illustrates an alternative, super-pixel arrangement wherein the array is stepped at a 45° angle. In this instance, an appropriate complete image may be fabricated, again after interleaving.

FIGURE 10 teaches a scheme to step an array to achieve a 3X resolution enhancement with horizontal stepping. A portion 80 evidences a structure of a super-pixel. From FIGURE 10, it will be appreciated that one may also step an array at a 45° angle in a way similar to what is described with FIGURE 9 above.

The super-pixel system described herein may be generalized to achieve any multiple (N) times resolution enhancement with an array of a given pixel resolution. For an N times resolution enhancement, one may suitably implement a super-pixel that has N neighboring pixels (see FIGURE 11). Each pixel is provided with a square sensor that has a fill factor of $1/N^2$ or larger, for anti-aliasing purposes. The centers are positioned against one side of the pixels in which they reside with a vertical spacing of $1/N$ of a pixel size. A stepping direction is then chosen along a horizontal direction with a step size of $1/N$ of a pixel size. See FIGURE 11.

One may suitably use space left uncovered by sensors to build electronics at a pixel level without affecting an image quality of the sensor array. The pixel level electronics can be used for image correction, data processing or the like. The remaining area is also suitably left transparent for back illumination as is used in contact imaging.

One embodiment of the invention is using vibrating mirrors to linearly translate an image with respect to a sensor array. In FIGURE 12, the document 20 has light exposed thereto from flash lamps 12(a) and 12(b). Light directed from the flash lamps 12 is communicated to a document 20. Light reflected therefrom is communicated to from along optical axis y' . Light focused there through lens 22 is provided to a fixed mirror 74 and reflected to a vibrating mirror 76. Vibration of the mirror 76 is accomplished with a pusher 78 disposed at a free moving end of the mirror 76 rotating around a pivot 80. The vibrator pivots the mirror in an arcuate direction d about the pivot 80.

Light reflected from the vibrating mirror 76 is communicated to lens 32 and thereby focused to sensor ar-

ray 34. It will be appreciated from this description that the vibrating mirror 76 serves to alter a focal point f of light from lens 32 into varying positions along the sensor array 34.

In FIGURE 13, another embodiment is disclosed. In this embodiment, as before, components that are similar in function to those described earlier have maintained their numbering schemes. Flash lamps 12(a) and 12(b) illuminate documents 20. Light reflected from document 20 is projected along an optical axis y'' and through a lens 22. Suitable means (not illustrated) are provided to laterally translate the lens 22 along a direction d' , generally perpendicular to the optical axis y'' . The reciprocal, linear motion of the mirror 22 along the direction d' allows for translation of the image.

FIGURE 14 illustrates an example of a superpixel design for 3X resolution enhancement. Super-pixel design for other enhancement ratios will also be similar in format to that in the illustration of FIGURE 14. A primary consideration for super-pixel design is that one must meet design rules of fabrication. Thus, particulars are highly application specific, but follow from the illustrated example.

It will be appreciated that the illustrated super-pixel design of FIGURE 14 provides a basic template for other enhancement ratios. Each particular super-pixel design is application specific and must meet design rules for fabrication. It will also be appreciated that additional attention must be made to ensure that each pixel has the same, or substantially the same, electrical properties, such as capacitance, parasitic effects, and the like. For an array made for contact imaging, it is advantageous that one made sure each sensor in a superpixel structure has a similar transparent structure next to the sensor, as well as the same fill factor for a transparent region to ensure a uniform exposure of a document.

A horizontal stepping scheme has an advantage over diagonal stepping schemes, as well as those provided with rotating wedge(s) and/or mirror(s). The horizontal translation scheme involves linear motion and post-scan image processing is also rendered straightforward.

A horizontal translation scheme is suitably implemented by introducing linear motion with respect to a sensor array. This may be accomplished by mechanically moving the array or the document. The same effect may also be suitably achieved with a vibrating mirror. This particular architecture was described above in connection with FIGURE 12.

A variation in a system for stepping an array linearly for higher resolution is provided in FIGURE 15. This figure also evidences a 3X resolution enhancement. Again, it will be appreciated that the basic principle is the same for other ratios of enhancement. The array shown has a conventional, uniform pixel structure. In order to cover all imaged space within such an array, the array or image is stepped in an angle of 18.43° from a horizontal direction. A step size along the horizontal di-

rection is $1/3$ of a pixel size. In the figure the sensor does not coincide with a high resolution grid for six of nine step positions. Accordingly, an interpolation is provided for the scanned images (or exposures) onto the high resolution grid. This reduces the speed of an imager while allowing for use of concurrent imager designs at higher resolution.

In a general case, one may achieve an N times resolution enhancement with a conventional pixel design and a sensor size of d/N where d is a pixel size.

An array is stepped with respect to a document image at an angle θ equals $\arctan(1/N)$ and a horizontal step size of (d/N) .

The subject system is also readily adapted to color-image scanning. The system provides for colorimaging of a document at a high resolution with a reduction in total image data. It is to be appreciated that the human visual system is much less sensitive to high frequency components of chrominant than that of luminant. Thus, reproduction of a color image with a satisfying quality may be provided with low-frequency samplings of chrominant components of an image. Image quality is contingent upon the means by which final output format is accomplished. Such means include color laser printers, video monitors, phototypesetters and the like. Since color imaging provides so much data, it is often advantageous to complete an undersampling of color primaries to reduce the data to be processed and increase the speed of an imager.

An example of an implementation for a 2X resolution enhance color imaging scheme is provided in FIGURE 16. In this system, the array or image is stepped with the pattern described above with the stepping-within-a-pixel scheme to enhance resolution. The pattern is stepped through a plurality of times to acquire colors primaries of the image. A higher ratio of resolution enhancement is obtained by employing a stepping pattern like that noted in FIGURE 6 above. A suitable imaging system may be found with the schematics described in connection with FIGURES 2 and 7, above. It also is to be appreciated that color filters are switched in front of flash lamps in synchronization with the exposures.

Since the human visual system is less sensitive to high-frequency components of color image chrominant, the imager is first stepped through four sensor positions to acquire four frames of black and white images (using no color filters). On a second pass of the array stepping, the imager acquires red, blue and green primaries while the sensor is at position 1, 2, and 3 respectively. From the three primaries, the chrominant images u , v in the Luv system, are calculated. For an approximation, one may assume that the primary is acquired at different sensor positions given a reasonable representation of primaries of an entire pixel at the given pixel resolution. Thus, a high-resolution luminant image is provided from four frames of black and white images and two low-resolution chrominate images. Interpolation then provides a low resolution, u , v images to high resolution grids.

Thus, provided as a complete color-imaging of a document with seven frames of images instead of 12 frames. A factor of 1.7 improvement in speed and data storage requirement therefore results. It is to be appreciated that the improvement in speed and storage increases for a higher ratio of resolution enhancement with the above-described implementation. However, the image quality of the scanned image will decrease correspondingly.

The color image, the example of FIGURE 16 was provided with a 2X enhancement in resolution. While the chrominants are acquired at the lower resolution, the resultant image quality changing is often negligible for many applications, such as in color laser printing.

Color imaging is also suitably accomplished with rotating filters and linear motion stepping of a document image with respect to the sensor array, as described in detail below. As such an embodiment, one captures a black and white image of a document at a fully enhanced resolution with white illumination in a first pass of the reciprocal motion. Thereafter, one captures a red, a green and a blue image in a stepping position 1, 2 and 3 respectively in a second pass of the relative motion of the array. (Additional color primary sets may also be implemented). At this point, one may derive a high-resolution luminant image with a lower resolution chrominant image from lower resolution color images of the document.

Color exposures of a document are not limited to the above-described step positions 1, 2, and 3. Certain applications allow for a timing of color exposures or even an increase in number of color exposures to achieve better color reproduction. This system may be applied to both the above-described super-pixel structured array, as well as to a conventional array. As evidenced from FIGURES 8, 9, 10 and 15, it does not matter when the color exposures occur. When N , the resolution enhancement factor, is greater than 2, a suitable timing of color exposures may be chosen for an even distribution of chrominant sampling.

From the foregoing systems, it will be appreciated that fabrication difficulties limit ultimate pixel resolution of a two-dimensional sensor array. One may achieve much higher resolution imaging by imaging a document several times while moving a document image with respect to a sensor array. A resolution of the final, interpolated image has a resolution defined by a step size which is advantageously chosen to be comparable to the sensor size. Image movement may be introduced by either moving the document or array mechanically, or using rotating wedges or mirrors. A super-pixel structure with a small sensor size allows one to achieve a resolution much higher than pixel resolution without pushing design rules for an array. The disclosed system apply the highspeed advantage of a two-dimensional sensor array to improve resolution of an imaging system.

In addition, using a fact that human, visual systems are less sensitive to high-frequency components in

chrominants of a color image, the system provides a technique that allows one to enhance resolution of color imaging with a two-dimensional array with reduced image data.

All of the techniques described in this proposal may be implemented with two-dimensional amorphous silicon sensor arrays which are provided in commercially available products.

Claims

1. An enhanced resolution image scanner comprising:

an array (34) of sensors, each sensor of the array adapted to generate a signal representative of a first subportion of a selected pixel of an associated specimen (20); and
orientation means for orienting each of the sensors relative to the associated specimen so as to generate a second signal representative of at least a second, unique subportion of each selected pixel.

2. An enhanced resolution image scanner as claimed in claim 1, wherein the orientation means includes:

directing means for directing each of the sensors relative to the associated specimen so as to generate the second signal therefrom with the second, unique subportion being from the same pixel from which it obtained the first subportion and, preferably, wherein the directing means is comprised of first and second rotating translucent wedges having a common optical axis disposed between pixels of the associated specimen and the sensor array; and wherein the image scanner further comprises, a first lens, sharing the common optical axis, disposed between the rotating translucent wedges and the associated specimen; and a second lens, sharing the common optical axis, disposed between the rotating translucent wedges and the sensor array; or wherein the directing means is comprised of:

first and second rotating mirrors disposed in an optical path between pixels of the associated specimen and the sensor array;
a first lens disposed to focus light from the associated specimen to the first rotating mirror; and
a second lens disposed to focus light from the second rotating mirror to the sensor array; or wherein: the directing means is comprised of a stepper adapted to obtain the second signal from a linearly displaced position along the associated specimen; and
the stepper is comprised of a mechanical trans-

lator adapted for selectively translating the sensor array relative to the associated specimen.

3. The enhanced resolution image scanner as claimed in claim 1, wherein the orientation means includes:

directing means for directing each of the sensors relative to the associated specimen so as to generate the second signal therefrom relative to at least one different chrominant content of the selected pixel of the associated specimen.

4. A method of obtaining enhanced scanned image data including:

focussing light from an illuminated specimen on to a directing means;
focussing light from the directing means to a sensor array (34);
selectively orienting, via the directing means, each of the sensors relative to the associated specimen;
generating a first signal representative of a first subportion of a selected pixel of the illuminated specimen; and
generating a second signal representative of a second portion of a selected pixel of the illuminated specimen, the second portion being different from the first subportion.

5. A method as claimed in claim 4, wherein:

the step of selectively orienting further includes the step of rotating first and second rotating translucent wedges having a common optical axis disposed between pixels of the associated specimen and the sensor array; and
the step of rotating includes the step of rotating the first rotating translucent wedge at a first angular velocity and the second rotating translucent wedge at a second angular velocity different from the first angular velocity; or wherein the step of selectively orienting further includes:
the step of rotating first and second mirrors having a common optical path disposed between pixels of the associated specimen and the sensor array; and
the step of rotating the first rotating mirror at a first angular velocity and the second rotating mirror at a second angular velocity different from the first angular velocity; or wherein the step of selectively orienting includes the steps of:
directing light reflected from the associated specimen to a first mirror;
receiving light reflected from the first mirror to a second mirror from which it is reflected to a second lens;

focussing light reflected from the second mirror through the second lens to the sensor array; and pivoting at least one of the first and second mirrors on a selected axis to provide the displaced position; or wherein the step of selectively orienting includes the steps of:
projecting, through a projection lens, an associated specimen onto the sensor array; and displacing, through a translator, the projection lens laterally to provide the displaced position.

6. An enhanced resolution image scanner comprising:

an array of sensors (34), each sensor of the array adapted to generate a signal representative of a first subportion of a selected pixel of an associated specimen;
orientation means for rotately orienting each of the sensors relative to the associated specimen so as to generate a second signal representative of at least a second, unique subportion of each selected pixel in accordance with the relation,

$$x = A \sin (2\pi f_1 t) + B \sin (2\pi f_2 + \phi); \text{ and}$$

$$y = A \cos (2\pi f_1 t) + B \cos (2\pi f_2 + \phi)$$

wherein A and B represent amplitudes of trajectory displacement and wherein f_1 and f_2 are the effective rotation frequencies of the sensors and the associated specimen, respectively;
wherein a selection of parameters A, B, ϕ , f_1 , and f_2 are such that the trajectory of the sensor position overlap to a pixel grid that has an enhanced resolution.

7. An enhanced resolution image scanner as claimed in claim 6, wherein the stepper is comprised of a mechanical translator adapted for selectively translating the sensor array relative to the associated specimen, the orientation means including at least one of:

means for moving at least one of the document and the sensor array;
means for rotating at least one translucent wedge disposed in an optical path between the sensor array and the specimen; and
means for rotating at least one mirror disposed in an optical path between the sensor array and the specimen; or wherein the stepper includes means for directing each of the sensors relative to the associated specimen to the next pixel being displaced linearly adjacent to the selected

pixel.

8. An enhanced resolution scanner as claimed in claim 3, wherein the orientation means further includes means for generating the second signal by selectively undersampling the enhancement content of the selected pixel of the associated specimen.

9. An enhanced resolution scanner as claimed in claim 1, wherein each sensor of the array has a selected orientation relative to each selected pixel such that the second signal is acquired by linearly displacing the sensor array relative to the specimen via the orientation means.

10. An enhanced resolution scanner as claimed in claim 9, wherein the linearly displacing is parallel to a linear array of the array of sensors, and, preferably, wherein the linearly displacing is at an angle of approximately 45 relative to a linear array of the array of sensors.
